

Path-Dependence of Leveraged ETF Returns*

Marco Avellaneda[†] and Stanley Zhang[†]

Abstract. It is well known that leveraged exchange-traded funds (LETFs) do not reproduce the corresponding multiple of index returns over extended (quarterly or annual) investment horizons. For instance, in 2008 and early 2009, most LETFs underperformed the corresponding static strategies. In this paper, we study this phenomenon in detail. We give an exact formula linking the return of a leveraged fund with the corresponding multiple of the return of the unleveraged fund and its realized variance. This formula is tested empirically over quarterly horizons for 56 leveraged funds (44 double-leveraged and 12 triple-leveraged) using daily prices since January 2008 or since inception, according to the fund considered. The results indicate excellent agreement between the formula and the empirical data. The study also shows that leveraged funds can be used to replicate the returns of the underlying index, provided we use a dynamic rebalancing strategy. Empirically, we find that rebalancing frequencies required to achieve this goal are moderate—on the order of one week between rebalancings. Nevertheless, this need for dynamic rebalancing leads to the conclusion that LETFs as currently designed may be unsuitable for buy-and-hold investors.

Key words. ETFs, leveraged ETFs, volatility

1. Introduction. Leveraged exchange-traded funds (LETFs) are relative newcomers to the world of exchange-traded funds (ETFs).¹ An LETF tracks the value of an index, a basket of stocks, or another ETF, with the additional feature that it uses leverage. For instance, the ProShares Ultra Financial ETF (UYG) offers double exposure to the Dow Jones U.S. Financials index. To achieve this, the manager invests two dollars in a basket of stocks tracking the index per each dollar of UYG's net asset value, borrowing an additional dollar. This is an example of a long LETF. Short LETFs, such as the ProShares UltraShort Financial ETF (SKF), offer a negative multiple of the return of the underlying ETF. In this case, the manager sells short a basket of stocks tracking the Dow Jones U.S. Financials index (or equivalent securities) to achieve a short exposure in the index of two dollars per each dollar of NAV ($\beta = -2$). In both cases, the fund's holdings are rebalanced daily.²

¹To our knowledge, the first issuer of leveraged ETFs was Rydex in late 2006.

²The description of the hedging mechanism given here is not intended to be exact, but rather to illustrate the general approach used by ETF managers to achieve the targeted leveraged long and short exposures. For instance, managers can trade the stocks that compose the ETFs or indices, or enter into total-return swaps to synthetically replicate the returns of the index that they track. The fact that the returns are adjusted daily is important for our discussion. Recently Direxion Funds, an LETF manager, has announced the launch of products with monthly rebalancing.

It has been empirically established that if we consider investments over extended periods of time (e.g, three months, one year, or more), there are significant discrepancies between LETF returns and the returns of the corresponding leveraged buy-and-hold portfolios composed of index ETFs and cash [7]. Since early 2008, the quarterly performance of LETFs over any period of 60 business days has been inferior to the performance of the corresponding static leveraged portfolios for many leveraged/unleveraged pairs tracking the same index. There are a few periods where LETFs actually outperform, so this is not just a one-sided effect.

For example, a portfolio consisting of two dollars invested in I-Shares Dow Jones U.S. Financial Sector ETF (IYF) and short one dollar can be compared with an investment of one dollar in UYG. Figures 1 and 2 compare the returns of UYG and a twice-leveraged buy-and-hold strategy with IYF, considering all 60-day periods (overlapping) since February 2, 2008. For convenience, we present returns in arithmetic and logarithmic scales. Figures 3 and 4 display the same data for SKF and IYF.

Figure 1. 60-day returns for UYG versus leveraged 60-day return of IYF. ($X = 2\text{Ret.}(IYF)$; $Y = \text{Ret.}(UYG)$). We considered all 60-day periods (overlapping) between February 2, 2008 and March 3, 2009. The concentrated cloud of points near the 45-degree line corresponds to 60-day returns prior to September 2008, when volatility was relatively low. The remaining points correspond to periods when IYF was much more volatile.

Observing Figures 1 and 3, we see that the returns of the LETFs have predominantly underperformed the static leveraged strategy. This is particularly the case in periods when returns are moderate and volatility is high. LETFs outperform the static leveraged strategy only when returns are large and volatility is small. Another observation is that the historical underperformance is more pronounced for the short LETF (SKF).

These charts can be partially explained by the mismatch between the quarterly investment horizon and the daily rebalancing frequency; yet there are several points that deserve attention.

First, we notice that, due to the daily rebalancing of LETFs, the geometric (continuously compounded) relation

$$\log \text{ret.}(\text{LETF}) \approx \beta \log \text{ret.}(\text{ETF})$$

Figure 2. Same as in Figure 1, but returns are logarithmic, i.e., $X = 2\ln(IYF_t/IYF_{t-60})$, $Y = \ln(UYG_t/UYG_{t-60})$.

Figure 3. Overlapping 60-day returns of SKF compared with the leveraged returns of the underlying ETF, overlapping, between February 2, 2008 and March 3, 2009. ($X = -2\text{Ret.}(IYF)$; $Y = \text{Ret.}(SKF)$.)

is more appropriate than the arithmetic (simply compounded) relation

$$\text{ret.}(LETF) \approx \beta \text{ret.}(ETF), \quad \beta = \pm 2.$$

This explains the apparent alignment of the data points once we pass to logarithmic returns in Figures 2 and 4.

Second, we notice that the data points do not fall on the 45-degree line; they lie for the most part below it. This effect is due to volatility. It can be explained by the fact that

Figure 4. Comparison of logarithmic returns of SKF with the corresponding log-returns of IYF. $X = -2\ln(IYF_t/IYF_{t-60})$; $Y = \ln(SKF_t/SKF_{t-60})$.

the LETF manager must necessarily “buy high and sell low” in order to enforce the target leverage requirement. Therefore, frequent rebalancing will lead to underperformance for the LETF relative to a static leveraged portfolio. The underperformance will be larger in periods when volatility is high, because daily rebalancing in a more volatile environment leads to more round-trip transactions, all other things being equal.

Thus, we find that holders of LETFs have an inherent exposure to the realized volatility of the underlying index, or to the volatility of the LETF itself. This effect is quantified using a simple model in section 2. We derive an exact formula for the return of an LETF as a function of its expense ratio, the applicable rate of interest, and the return and realized variance of an unleveraged ETF tracking the same index (the “underlying ETF,” for short). In particular, we show that the holder of an LETF has a negative exposure to the realized variance of the underlying ETF. Since the expense ratio and the funding costs can be determined in advance with reasonable accuracy, the main factor that affects LETF returns is the realized variance. In section 3, we empirically validate the formula on a set of 56 LETFs with double and triple leverage, using all the data since their inception. The empirical study suggests that the proposed formula is very accurate.³

In the last section, we show that it is possible to use LETFs to replicate a predefined multiple of the underlying ETF returns, provided that we use dynamic hedging strategies. Specifically, in order to achieve a specified multiple of the return of the underlying index or ETF using LETFs, we must adjust the portfolio holdings in the LETF dynamically, according

³Interestingly, similar considerations about volatility exposure apply to a class of over-the-counter (OTC) products known as Constant Proportion Portfolio Insurance (CPPI). These products are typically embedded in structured notes and other derivatives marketed by insurance companies and banks (see, for instance, Black and Perold [3] and Bertrand and Prigent [2]). Although not directly relevant to this study, the parallel between the behavior of listed LETFs and OTC products may be of independent interest.

to the amount of variance realized up to the hedging time by the index, as well as the level of the index. We derive a formula for the dynamic hedge-ratio, which is closely related to the model for LETFs, and we validate it empirically on the historical data for 44 double-leveraged LETFs. This last point, dynamic hedging, provides an interesting connection between LETFs and options.

After completing this paper, we found out that analogous results were obtained independently in a note issued by Barclays Global Investors [4], which contains a formula similar to (10) without including finance and expense ratios. To the best of our knowledge, the empirical testing of the formula over a broad universe of existing LETFs and the application to dynamic hedging using LETFs are new.

2. Modeling LETF returns. We denote the spot price of the underlying ETF by S_t , the price of the LETF by L_t , and leverage ratio by β . For instance, a double-leveraged long ETF will correspond to $\beta = 2$, whereas a double-leveraged short ETF corresponds to $\beta = -2$.

2.1. Discrete-time model. Assume a model where there are N trading days, and denote by R_i^S and R_i^L , $i = 1, 2, \dots, N$, the one-day returns for the underlying ETF and the LETF, respectively. The LETF provides a pro forma daily exposure of β dollars of the underlying security per dollar under management.⁴ Accordingly, there is a simple link between R_i^S and R_i^L . If the LETF is bullish ($\beta > 1$), then

$$(1) \quad R_i^L = \beta R_i^S - \beta r \Delta t - f \Delta t + r \Delta t = \beta R_i^S - ((\beta - 1)r + f) \Delta t,$$

where r is the reference interest rate (for instance, 3-month LIBOR), f is the expense ratio of the LETF, and $\Delta t = 1/252$ represents one trading day.

If the LETF is bearish ($\beta \leq -1$), the same equation holds with a small modification, namely,

$$(2) \quad R_i^L = \beta R_i^S - \beta(r - \lambda_i) \Delta t - f \Delta t + r \Delta t = \beta R_i^S - ((\beta - 1)r + f - \beta \lambda_i) \Delta t,$$

where $\lambda_i \Delta t$ represents the cost of borrowing the components of the underlying index or the underlying ETF on day i . By definition, this cost is the difference between the reference interest rate and the “short rate” applied to cash proceeds from short sales of the underlying ETF. If the ETF, or the stocks that it holds, are widely available for lending, the short rate will be approximately equal to the reference rate and the borrowing costs are negligible.⁵

Let t be a period of time (in years) covering several days ($t = N\Delta$). Compounding the returns of the LETF, we have

$$(3) \quad L_t = L_0 \prod_{i=1}^N (1 + R_i^L).$$

⁴In the sense that this does not account for the costs of financing positions and management fees.

⁵We emphasize the cost of borrowing, since we are interested in LETFs which track financial indices. The latter have often been hard-to-borrow since July 2008. Moreover, broad market ETFs such as SPY have also been sporadically hard-to-borrow in the last quarter of 2008; see Avellaneda and Lipkin [1].

Substituting the value of R_t^L into (1) or (2) (according to the sign of β), we obtain a relation between the prices of the LETF and the underlying asset. In fact, we show in the appendix that, under mild assumptions, we have

$$(4) \quad \frac{L_t}{L_0} \approx \left(\frac{S_t}{S_0} \right)^\beta \exp \left\{ \frac{\beta - \beta^2}{2} V_t + \beta H_t + ((1 - \beta)r - f) t \right\},$$

where

$$(5) \quad V_t = \sum_{i=1}^N \left(R_i^S - \overline{R^S} \right)^2 \quad \text{with} \quad \overline{R^S} = \frac{1}{N} \sum_{i=1}^N R_i^S,$$

i.e., V_t is the realized variance of the price over the time-interval of interest, and where

$$(6) \quad H_t = \sum_{i=1}^N \lambda_i \Delta t$$

represents the accumulated cost of borrowing the underlying stocks or ETF. This cost is obtained by subtracting the average applicable short rate from the reference interest rate each day and accumulating this difference over the period of interest. In addition to these two factors, formula (4) also shows the dependence on the funding rate and the expense ratio of the underlying ETF. The symbol “ \approx ” in (4) means that the difference is small in relation to the daily volatility of the ETF or LETF. In the following section, we exhibit an exact relation, under the idealized assumptions that the price of the underlying ETF follows an Ito process and that rebalancing is done continuously.

2.2. Continuous-time model. To clarify the sense in which (4) holds, it is convenient to derive a similar formula assuming that the underlying ETF price follows an Ito process. To wit, we assume that S_t satisfies the stochastic differential equation

$$(7) \quad \frac{dS_t}{S_t} = \sigma_t dW_t + \mu_t dt,$$

where W_t is a standard Wiener process and σ_t, μ_t are, respectively, the instantaneous price volatility and drift. The latter processes are assumed to be random and nonanticipative with respect to W_t .⁶

Mimicking (1) and (2), we observe that if the LETF is bullish, the model for the return of the leveraged fund is now

$$(8) \quad \frac{dL_t}{L_t} = \beta \frac{dS_t}{S_t} - ((\beta - 1)r + f) dt.$$

If the LETF is bearish, the corresponding equation is

$$(9) \quad \frac{dL_t}{L_t} = \beta \frac{dS_t}{S_t} - ((\beta - 1)r - \beta \lambda_t + f) dt,$$

⁶They are not assumed to be deterministic functions or constants.

where λ_t represents the cost of borrowing the underlying ETF or the stocks that make up the ETF. In the appendix, we show that the following formula holds:

$$(10) \quad \frac{L_t}{L_0} = \left(\frac{S_t}{S_0}\right)^\beta \exp \left\{ ((1-\beta)r - f)t + \beta \int_0^t \lambda_s ds + \frac{(\beta - \beta^2)}{2} \int_0^t \sigma_s^2 ds \right\},$$

where we assume implicitly that $\lambda_t = 0$ if $\beta > 0$.

Formulas (4) and (10) convey essentially the same information if we define

$$V_t = \int_0^t \sigma_s^2 ds \quad \text{and} \quad H_t = \int_0^t \lambda_s ds.$$

The only difference is that (4) is an approximation which is valid for $\Delta t \ll 1$, whereas (10) is exact if the ETF price follows an Ito process. These equations show that the relation between the values of an LETF and its underlying ETF depends on

- the *funding rate*,
- the *expense ratio* for the LETF,
- the *cost of borrowing shares* in the case of short LETFs,
- the *convexity* (power law) associated with the leverage ratio β , and
- the *realized variance* of the underlying ETF.

The first two items require no explanation. The third follows from the fact that the manager of a bearish LETF may incur additional financing costs to maintain short positions if components of the underlying ETF or the ETF itself are hard-to-borrow. The last two items are more interesting: (i) due to daily rebalancing of the beta of the LETF, we find that the prices of an LETF and a nonleveraged ETF are related by a power law with power β , and (ii) the realized variance of the underlying ETF plays a significant role in determining the LETF returns.

The dependence on the realized variance might seem surprising at first. It turns out that the holder of an LETF has negative exposure to the realized variance of the underlying asset. This holds regardless of the sign of β . For instance, if the investor holds a double-long LETF, the term corresponding to the realized variance in formula (10) is

$$-\frac{(2^2 - 2)}{2} \int_0^t \sigma_s^2 = - \int_0^t \sigma_s^2.$$

In the case of a doubly bearish fund, the corresponding term is

$$-\frac{((-2)^2 - (-2))}{2} \int_0^t \sigma_s^2 = -3 \int_0^t \sigma_s^2.$$

We note, in particular, that the dependence on the realized variance is stronger in the case of the double-short LETF.

3. Empirical validation. To validate the formula in (10), we consider 56 LETFs which currently trade in the U.S. markets. Of these, we consider 44 LETFs issued by ProShares, consisting 22 Ultra Long and 22 UltraShort ETFs.⁷ Table 1 gives a list of the Proshares

⁷For information about ProShares, see <http://www.proshares.com>.

LETFs, their tickers, together with the corresponding sectors and their ETFs. We consider the evolution of the 44 LETFs from January 2, 2008 to March 20, 2009, a period of 308 business days.

We also consider 12 triple-leveraged ETFs issued by Direxion Funds.⁸ Direxion's LETFs were issued later than the ProShares funds, in November 2008; they provide a shorter historical record to test our formula. Nevertheless, we include the 3X Direxion funds for the sake of completeness and also because they have triple leverage (Table 2).

⁸See <http://www.direxionfunds.com>.

We define the tracking error

$$(11) \quad \epsilon(t) = \frac{L_t}{L_0} - \left(\frac{S_t}{S_0} \right)^\beta \exp \left\{ \frac{\beta - \beta^2}{2} V_t + \beta H_t + ((1 - \beta)r - f)t \right\},$$

where V_t is the accumulated variance, H_t is the accumulated borrowing costs (in excess of the reference interest rate), r is the interest rate, and f is the management fee for the underlying ETF. The instantaneous volatility is modeled as the standard deviation of the returns of the underlying ETF sampled over a period of 5 days preceding each trading date:

$$(12) \quad \hat{\sigma}_s^2 = \frac{1}{5} \sum_{i=1}^5 (R_{(s/\Delta t)-i}^{(S)})^2 - \left(\frac{1}{5} \sum_{i=1}^5 R_{(t/\Delta t)-i}^{(S)} \right)^2, \quad 0 \leq s \leq t.$$

For the interest rates and expense ratio, we use the 3-month LIBOR rate published by the Federal Reserve Bank (H.15 Report) and the expense ratio for the Proshares LETFs published in the prospectus. In all cases, we set $\lambda_t = 0$; i.e., we do not take into account stock-borrowing costs explicitly.

The empirical results for ProShares are summarized in Tables 3 and 4.

In the case of long LETFs, we find that the average of the tracking error $\epsilon(t)$ over the simulation period is typically less than 100 basis points. The standard deviation is also on the order of 100 basis points, with a few slightly higher observations. This suggests that the formula (10), using the model for stochastic volatility in (12), gives a reliable model for the relation between the LETFs and the underlying ETFs across time.

In the case of short ETFs, we also assume that $\lambda_t = 0$ but expect a slightly higher tracking error, particularly between July and November of 2008, when restrictions for short selling in U.S. stocks were put in place. We observe higher levels for the mean and the standard deviation of the tracking error and some significant departures from the exact formula during the period of October and November of 2008, especially in Financials, which we attribute to short selling constraints. The tracking errors for the Direxion triple-leveraged ETFs have higher standard deviations, which is not surprising given that they have higher leverage (Tables 5 and 6). We note, in particular, that the errors for FAS and FAZ are the largest, which is consistent with the fact that they track financial stocks.

The conclusion of the empirical analysis is that the formula (10) explains well the behavior of the price of LETFs and the deviations between LETF returns and the returns of the underlying ETFs.

4. Consequences for buy-and-hold investors.

4.1. Comparison with buy-and-hold: Break-even levels. Formula (10) suggests that an investor who is long an LETF has a “time-decay” associated with the realized variance of the underlying ETF. In other words, if the price of the underlying ETF does not change significantly over the investment horizon, but the realized volatility is large, the investor in the LETF will underperform the corresponding leveraged return on the underlying ETF. On the contrary, if the underlying ETF makes a sufficiently large move in either direction, the investor will outperform the underlying ETF.

Table 3

Double-leveraged Ultra Long ETFs. Average tracking error (11) and standard deviation obtained by applying formula (10) to the Proshares long LETFs from January 2, 2008 to March 20, 2009. Notice that the average tracking error is for the most part below 100bps and the standard deviation is comparable. In particular, the standard deviation is inferior to the daily volatility of these assets, which often exceeds 100 basis points as well. This suggests that formula (10) gives the correct relation between the NAV of the LETFs and their underlying ETFs.

Underlying ETF	Tracking error (average, %)	Standard deviation (%)	Leveraged ETF
QQQQ	0.04	0.47	QLD
DIA	0.00	0.78	DDM
SPY	-0.06	0.40	SSO
IJH	-0.06	0.38	MVV
IJR	1.26	0.71	SAA
IWM	1.26	0.88	UWM

IYR	1.64	1.86	URE
IYW	0.51	0.55	ROM
IDU	0.25	0.55	UPW

Consider an investor who buys one dollar of an LETF and simultaneously shorts β dollars of the underlying ETF (where shorting a negative amount means buying). For simplicity, we assume that the interest rate, fees, and borrowing costs are zero.

If we use (10), the equity in the investor's account will be equal to

$$(13) \quad E(t) = \left(\frac{S_t}{S_0}\right)^\beta e^{-\frac{(\beta^2-\beta)}{2}V_t} - \beta\frac{S_t}{S_0} - (1-\beta),$$

including the cash credit or debit from the initial transaction. To be concrete, we consider the case of a double-long and a double-short separately. Setting $Y = E(t)$ and $X = \frac{S_t}{S_0}$, we obtain

$$(14) \quad \begin{aligned} Y &= e^{-V_t} X^2 - 2X + 1, & \beta &= 2, \\ Y &= e^{-3V_t} \frac{1}{X^2} + 2X - 3, & \beta &= -2. \end{aligned}$$

In the case of the double-long ETFs, the equity behaves like a parabola in $X = S_t/S_0$ with a curvature tending to zero exponentially as a function of the realized variance. The investor

Table 4

Double-leveraged Ultra Short ETFs. Same as in Table 3, for double-short LETFs. Notice that the tracking error is relatively small, but there are a few funds where the tracking error is superior to 200 basis points. We attribute these errors to the fact that May ETFs, particularly in the Financial and Energy sectors, and the stocks in their holdings were hard-to-borrow from July to November 2008.

Underlying ETF	Tracking error (average, %)	Standard deviation (%)	Leveraged ETF

Table 5

Triple-Leveraged bullish ETFs. Average tracking errors and standard deviations for triple-leveraged long ETFs analyzed here, since their inception in November 2008.

Underlying ETF/index	Tracking error (average, %)	Standard deviation (%)	3X bullish LETF
IWB	0.44	0.55	BGU
IWM	0.81	0.75	TNA
RIFIN.X	3.67	2.08	FAS
RIENG.X	2.57	0.70	ERX
EFA	1.26	2.32	DZK
EEM	1.41	1.21	EDC

is therefore long convexity (Gamma, in options parlance) and short variance; hence he incurs time-decay (Theta). In the case of double-shorts, the profile is also a convex curve, which has convexity concentrated mostly for $X \ll 1$, and a much faster time-decay. From (14), we find that the break-even levels of X , V_t needed for achieving a positive return by time t are as follows.

Table 6

Triple-Leveraged bearish ETFs. Average tracking errors and standard deviations for triple-leveraged short ETFs analyzed here, since their inception in November 2008. Notice again that the errors for financials and energy are slightly higher than the rest.

Underlying ETF/index	Tracking error average, (%)	Standard deviation (%)	3X bearish LETF
IWB	-0.08	0.64	BGZ
IWM	0.65	0.76	TZA
RIFIN.X	-1.63	4.04	FAZ
RIENG.X	-1.41	1.01	ERY
EFA	-1.54	1.86	DPK
EEM	0.49	1.43	EDZ

- Double-long LETF:

$$\begin{aligned}
 X > X_+ &= e^{V_t} \left(1 + \sqrt{1 - e^{-V_t}} \right), \\
 X < X_- &= e^{V_t} \left(1 - \sqrt{1 - e^{-V_t}} \right).
 \end{aligned}$$

- Double-short LETF:

(15) X_+, X_- are the positive roots of the cubic equation $2X^3 - 3X^2 + e^{-3V_t} = 0$.

A similar analysis can be made for triple-leveraged ETFs. The main observation is that, regardless of whether the LETFs are long or short, they underperform the static leveraged strategy unless the returns of the underlying ETFs overcome the above volatility-dependent break-even levels. These levels are further away from the initial level as the realized variance increases.

4.2. Targeting investment returns using dynamic strategies with LETFs. A strong motivation for using LETFs is to take advantage of leverage when gaining exposure to an index.⁹ In this section we observe that it is possible to achieve a predetermined target return for the *underlying ETF* (e.g., IYF) using a *dynamic strategy with LETFs* (UYG or SKF).

Suppose that an agent is long n shares of the underlying ETF and short Δ shares of the corresponding β -leveraged ETF. The one-period return of this portfolio is

(16)
$$\begin{aligned}
 d\Pi &= ndS - \Delta dL \\
 &= nS \frac{dS}{S} - \Delta L \frac{dL}{L} \\
 &= nS \frac{dS}{S} - \Delta L \beta \frac{dS}{S} + (\text{carry terms}).
 \end{aligned}$$

⁹For investors subject to Regulation T margin requirements, the maximum allowed leverage for equities is 2. The use of a double-leveraged ETF would produce, accordingly, a leverage of 4 vis à vis the reference index. However, effective December 1, 2009, FINRA has introduced new margin requirements on LETFs to avoid such overleveraging by retail investors [9].

It follows that the choice of $\Delta = \frac{nS}{L}$ should give a portfolio without market risk. Based on this observation, consider an investor with an initial endowment of Π_0 dollars and a dynamic strategy which invests

$$\delta_t = \Pi_0 \frac{1}{\beta} \frac{S_t}{S_0}$$

dollars in the LETF with multiplier β . For simplicity, we assume $\lambda = f = 0$. Let us denote the value of his position at time t by Π_t . The change in value of this position across time, funded at the rate r , satisfies

$$\begin{aligned} (17) \quad d\Pi_t &= r\Pi_t dt + \delta_t \frac{dL_t}{L_t} - r\delta_t dt \\ &= r\Pi_t dt + \delta_t \left(\beta \frac{dS_t}{S_t} + (1 - \beta)r dt \right) - r\delta_t dt \\ &= r\Pi_t dt + \Pi_0 \frac{1}{\beta} \frac{S_t}{S_0} \left(\beta \frac{dS_t}{S_t} + (1 - \beta)r dt \right) - r\delta_t dt \\ &= r\Pi_t dt + \Pi_0 \frac{dS_t}{S_0} + \Pi_0 \frac{1}{\beta} \frac{S_t}{S_0} r dt - \Pi_0 \frac{S_t}{S_0} r dt - \Pi_0 \frac{1}{\beta} \frac{S_t}{S_0} r dt \\ (18) \quad &= r\Pi_t dt + \Pi_0 \frac{dS_t}{S_0} - \Pi_0 \frac{S_t}{S_0} r dt. \end{aligned}$$

Integrating this stochastic differential equation from $t = 0$ to $t = T$, the reader can verify that (18) implies that

$$(19) \quad \frac{\Pi_T}{\Pi_0} = \frac{S_T}{S_0}$$

for all T .

Accordingly, the agent can “replicate” the returns of the underlying stock over any maturity by dynamic hedging with LETFs, with essentially $\frac{1}{|\beta|}$ of the capital required to do the same trade in the underlying ETF.

However, in order to achieve his target return over an extended investment period using LETFs, the investor needs to rebalance his portfolio according to his Delta exposure. Because of this, dynamic replication with LETFs may not be suitable for many retail investors. On the other hand, this analysis will be useful to active traders, investment advisors, or issuers who manage LETFs with longer investment horizons, since we have shown that the latter can be “replicated” dynamically with LETFs which are rebalanced daily.

In Tables 7 and 8 we demonstrate the effectiveness of this dynamic replication method using different rebalancing techniques. We consider dynamic hedging in which we rebalance if the total Delta exceeds a band of 1%, 2%, 5%, and 10%, and also hedging with fixed time-steps of 1, 2, 5, or 15 business days. Table 9 indicates the expected number of days between rebalancing for strategies that are price-dependent. The results indicate that rebalancing when the Delta exposure exceeds 5% of notional give reasonable tracking errors. The corresponding average intervals between rebalancings can be large, which means that, in practice, one can achieve reasonable tracking errors without necessarily rebalancing the Delta daily or even weekly.

Table 7

Average tracking error, in % of notional, for the dynamic replication of 6-month returns using double-long LETFs with $m = \beta$. The first four columns correspond to rebalancing when the Delta reaches the edge of a band of $\pm x\%$ around zero. The last four columns correspond to rebalancing at fixed time intervals. The data used to generate this table corresponds, for each ETF, to all overlapping 6-month returns in the year 2008.

5. Conclusion. This study presents a formula for the value of an LETF in terms of the value of the underlying index or ETF. The formula is validated empirically using end-of-day data on 56 LETFs, of which 44 are double-leveraged and 12 are triple leveraged. This formula validates the fact that on log-scale LETFs will underperform the nominal returns by a contribution that is primarily due to the realized volatility of the underlying ETF. The formula also takes into account financing costs and shows that for short ETFs, the cost of borrowing the underlying stock may play a role as well, as observed in [1].

We also demonstrate that LETFs can be used for hedging and replicating unleveraged ETFs, provided that traders engage in dynamic hedging. In this case, the hedge-ratio depends on the realized accumulated variance as well as on the level of the LETF at any point in time. The path-dependence of leveraged ETFs makes them interesting for the professional investor, since they are linked to the realized variance and the financing costs. However, they may not be suitable for buy-and-hold investors who aim at replicating a particular index taking advantage of the leveraged provided, for the reasons explained above.

Addendum, October 27, 2009. Very recently, regulators have issued notices concerning the suitability of LETFs for buy-and-hold investors which are consistent with our findings. These include a Regulatory Notice by the Financial Instrument Regulatory Authority [8] and an alert by the U.S. Securities and Exchange Commission (July 2009). Also, a major issuer of

LETFs recently issued a paper addressing such concerns [5].

Appendix.

A.1. Discrete-time model (equation (4)). Set $a_i = (\beta - 1)r + f + \beta\lambda_i$, where λ_i is the cost of borrowing the underlying asset on day i (λ_i is zero if $\beta > 0$.) We assume that

$$R_i^S = \xi_i \sqrt{\Delta t} + \mu \Delta t,$$

where $\Delta t = 1/252$ and $\xi_i, i = 1, 2, \dots$, is a stationary process such that ξ_i has mean equal to zero and finite absolute moments of order 3. This assumption is consistent with many models of equity returns. Notice that we do not assume that successive returns are uncorrelated.

From (1), (2), and (3), we find using Taylor expansion that

$$\begin{aligned}
 \ln \left(\frac{L_t}{L_0} \right) &= \sum_i \ln (1 + R_i^L) \\
 &= \sum_i \ln (1 + \beta R_i^S - a_i \Delta t) \\
 (20) \quad &= \sum_i \left(\beta R_i^S - a_i \Delta t - \frac{\beta^2}{2} (R_i^S)^2 \right) + \sum_i (O(|R_i^S|^3) + O(|R_i^S| \Delta t)).
 \end{aligned}$$

Table 9

Average number of business days between portfolio rebalancing for the 6-month dynamic hedging strategy: The effect of changing the Delta band. Each column shows the average number of days between rebalancing the portfolio, assuming different Delta-bandwidth for portfolio rebalancing. For instance, the column with heading of 1% corresponds to a strategy that rebalances the portfolio each time the net delta exposure exceeds 1% of the notional amount. The expected number of days between rebalancing increases as the bandwidth increases.

ETF	1 %	2 %	5 %	10 %

IYE	1.79	3.43	12	40
IYR	1.62	3.16	17	30
IYW	2.00	3.53	40	NR
IDU	2.67	6.32	20	120

By the same token, we have

$$\begin{aligned}
 \beta \ln \left(\frac{S_t}{S_0} \right) &= \beta \sum_i \ln (1 + R_i^S) \\
 (21) \qquad \qquad \qquad &= \beta \sum_i \left(R_i^S - \frac{1}{2} (R_i^S)^2 \right) + \sum_t O((R_i^S)^3).
 \end{aligned}$$

Subtracting (22) from (21), we find that

$$\begin{aligned}
 \ln \left(\frac{L_t}{L_0} \right) - \beta \ln \left(\frac{S_t}{S_0} \right) &= - \sum_i \left(a_i \Delta t + \frac{\beta^2 - \beta}{2} (R_i^S)^2 \right) + \sum_i (O(|R_i^S|^3) + O(|R_i^S| \Delta t)) \\
 &= - \sum_i \left(a_i \Delta t + \frac{\beta^2 - \beta}{2} ((R_i^S)^2 - \mu^2 (\Delta t)^2) \right) \\
 &\quad + \sum_i (O(|R_i^S|^3) + O(|R_i^S| \Delta t) + O((\Delta t)^2)) \\
 (22) \qquad \qquad \qquad &= - \sum_i a_i \Delta t - \frac{\beta^2 - \beta}{2} V_t + \sum_i (O(|R_i^S|^3) + O(|R_i^S| \Delta t) + O((\Delta t)^2)).
 \end{aligned}$$

We show that the remainder in this last equation is negligible. In fact, we have

$$\begin{aligned}
 \sum_i |R_i^S|^3 &= \sum_i |\xi_i|^3 (\Delta t)^{3/2} \\
 &= \left(\frac{\sum_i |\xi_i|^3}{N} \right) t \sqrt{\Delta t} \\
 (23) \quad &\approx E(|\xi_1^3|) t \sqrt{\Delta t}
 \end{aligned}$$

and, similarly,

$$\begin{aligned}
 \sum_i |R_i^S| \Delta t &= \sum_i |\xi_i| (\Delta t)^{3/2} \\
 &= \left(\frac{\sum_i |\xi_i|}{N} \right) t \sqrt{\Delta t} \\
 (24) \quad &\approx E(|\xi_1|) t \sqrt{\Delta t}.
 \end{aligned}$$

Therefore, the contribution of the last sum in (23) is bounded by the first three moments of ξ_1 , multiplied by the investment horizon, t , and by $\sqrt{\Delta t}$. This means that if we neglect the last terms, for investment horizons of less than 1 year, the error is on the order of the standard deviation of the daily returns of the underlying ETF, which is negligible.

A.2. Continuous-time model (equation (10)). The above reasoning is exact for Itô processes, because it corresponds to $\Delta t \rightarrow 0$. To be precise, we consider (7), (8), and (9) and apply Itô's lemma to obtain

$$(25) \quad d \ln S_t = \frac{dS_t}{S_t} - \frac{\sigma_t^2}{2} dt$$

$$(26) \quad d \ln L_t = \beta \frac{dS_t}{S_t} - \frac{\beta^2 \sigma_t^2}{2} dt + ((\beta - 1)r + f + \beta \lambda_i) dt \quad (\lambda_i = 0 \text{ if } \beta > 0).$$

Multiplying (26) by β and subtracting it from (27), we obtain

$$(27) \quad d \ln L_t - \beta d \ln S_t = -\frac{(\beta^2 - \beta) \sigma_t^2}{2} dt + ((\beta - 1)r + f + \beta \lambda_i) dt,$$

which implies (10).

Acknowledgment. We thank two anonymous referees for pointing out the parallels between LETFs and over-the-counter CPPI products, as well as for pointing out a simplified proof of the dynamic replication scheme of section 4.2.
